Binary search trees
Binary trees

A tree = a leaf OR a node carrying two sub-trees.

Carries information at the leaves or at the nodes.

Information = element \(\rightarrow\) finite sets

Information = (key, value) pair \(\rightarrow\) finite maps, dictionaries
The algebraic view

With elements $x \in X$ at leaves:

$$A ::= [x] \quad \text{leaf}$$
$$\mid \langle A_1, A_2 \rangle \quad \text{node}$$

With elements $x \in X$ at nodes:

$$A ::= \bullet \quad \text{leaf}$$
$$\mid \langle A_1, x, A_2 \rangle \quad \text{node}$$

Direct translation to algebraic types
(OCaml, Haskell, ...) or inductive types (Coq, Agda, ...):

```ocaml
type 'a tree = Leaf of 'a | Node of 'a tree * 'a tree
```

```haskell
type 'a tree = Leaf | Node of 'a tree * 'a * 'a tree
```
A binary search tree = a binary tree with elements at nodes elements strictly increase from left to right (infix traversal).

(Note: we don’t draw branches leading to leaves. What looks like the leaf a is the trivial node ⟨•, a, •⟩ )
Inductive invariant: for every node $\langle A, b, C \rangle$,
the elements contained in the left sub-tree $A$ are $< b$
the elements contained in the right sub-tree $C$ are $> b$
Binary search in a BST

Membership in a finite set:
\[ \text{mem}(x, \bullet) = \text{false} \]
\[ \text{mem}(x, \langle A, b, C \rangle) = \begin{cases} \text{mem}(x, A) & \text{if } x < b \\ \text{true} & \text{if } x = b \\ \text{mem}(x, C) & \text{if } x > b \end{cases} \]

Looking up a key in a dictionary:
\[ \text{find}(x, \bullet) = \text{None} \]
\[ \text{find}(x, \langle A, (k, v), C \rangle) = \begin{cases} \text{find}(x, A) & \text{if } x < k \\ \text{Some}(v) & \text{if } x = k \\ \text{find}(x, C) & \text{if } x > k \end{cases} \]

Time: \( \mathcal{O}(h) \) where \( h \) is the height of the tree, i.e. the maximal length of a branch.
Insertion in a BST: imperative version

1. Search for the element to be inserted (here, g).
1. Search for the element to be inserted (here, $g$).
1. Search for the element to be inserted (here, g).

2. When reaching a leaf, replace it by the node ⟨•, g, •⟩.

Time: $\mathcal{O}(h)$, space: $\mathcal{O}(1)$. 
1. Search for the element to be inserted (here, $g$).
1. Search for the element to be inserted (here, g).
1. Search for the element to be inserted (here, g).
2. When reaching a leaf, **copy the path** from the root to this leaf, sharing sub-trees with the initial tree.
1. Search for the element to be inserted (here, \(g\)).
2. When reaching a leaf, **copy the path** from the root to this leaf, sharing sub-trees with the initial tree.
3. At the end of the copied path, add the node \(\langle \bullet, g, \bullet \rangle\).

Time: \(O(h)\), space: \(O(h)\).
Insertion in a BST: algebraic presentation

Adding an element to a finite set:

\[
\text{add}(x, \bullet) = \langle \bullet, x, \bullet \rangle
\]

\[
\text{add}(x, \langle A, b, C \rangle) = \begin{cases} 
\langle \text{add}(x, A), b, C \rangle & \text{if } x < b \\
\langle A, x, C \rangle & \text{if } x = b \\
\langle A, b, \text{add}(x, C) \rangle & \text{if } x > b
\end{cases}
\]

Inserting a (key, value) pair in a dictionary:

\[
\text{ins}(k, v, \bullet) = \langle \bullet, (k, v), \bullet \rangle
\]

\[
\text{ins}(k, v, \langle A, (k', v'), C \rangle) = \begin{cases} 
\langle \text{ins}(k, v, A), (k', v'), C \rangle & \text{if } k < k' \\
\langle A, (k, v), C \rangle & \text{if } k = k' \\
\langle A, (k', v'), \text{ins}(x, C) \rangle & \text{if } k > k'
\end{cases}
\]
let rec add x t =
  match t with
  | Leaf -> Node(Leaf, x, Leaf)
  | Node(a, b, c) ->
    if x < b then
      Node(add x a, b, c)
    else if x > b then
      Node(a, b, add x c)
    else
      t

The path copying takes place when returning from recursive calls, by evaluating the expressions Node(add x a, b, c) or Node(a, b, add x c).
A simple equational specification:

\[
\text{mem}(x, \text{add}(x, T)) = \text{true} \tag{1}
\]
\[
\text{mem}(x, \text{add}(y, T)) = \text{mem}(x, T) \quad \text{if } x \neq y \tag{2}
\]

A proof by structural induction over \( T \).

Base case for (1): \( \text{mem}(x, \text{add}(x, \bullet)) = \text{true} \).

Inductive case for (1): unroll definitions and analyze 3 cases

\[
\text{mem}(x, \text{add}(x, \langle A, b, C \rangle))) = \begin{cases} 
\text{mem}(x, \text{add}(x, A)) & \text{if } x < b \\
\text{true} & \text{if } x = b \\
\text{mem}(x, \text{add}(x, C)) & \text{if } x > b 
\end{cases}
\]

The result (1) follows from the induction hypothesis.

Exercise: prove (2).
Deletion in a BST

We search for the sub-tree \( \langle A, b, C \rangle \) carrying the element \( b \) to be removed, then replace it by a tree that contains the same elements as \( A \) and \( C \).

Idea: use the smallest element of \( C \) (or the largest element of \( A \)) as the root of this new tree.
Deletion in a BST

\[
\text{del}(x, \bullet) = \bullet
\]

\[
\text{del}(x, \langle A, b, C \rangle) = \begin{cases} 
\langle \text{del}(x, A), b, C \rangle & \text{if } x < b \\
\text{join}(A, C) & \text{if } x = b \\
\langle A, b, \text{del}(x, C) \rangle & \text{if } x > b 
\end{cases}
\]

\[
\text{join}(A, \bullet) = \text{join}(\bullet, A) = A
\]

\[
\text{join}(A, C) = \langle A, \text{min}(C), \text{delmin}(C) \rangle \quad \text{if } C \neq \bullet
\]

\[
\text{min}(\langle \bullet, b, C \rangle) = b \quad \text{delmin}(\langle \bullet, b, C \rangle) = C
\]

\[
\text{min}(\langle A, b, C \rangle) = \text{min}(A) \quad \text{delmin}(\langle A, b, C \rangle) = \langle \text{delmin}(A), b, C \rangle
\]
Other operations

Smallest element, largest element
⇒ usable as a priority queue.

If every sub-tree is annotated by its size:
which element has rank \( k \)? which rank has element \( x \)?
⇒ usable as an ordered sequence.

Set operations: union, intersection, difference, …
Set operations

Pattern: recurse on one of the two trees and split the other one.

\[
\text{union}(\bullet, T) = \text{union}(T, \bullet) = T
\]

\[
\text{union}(\langle A, b, C \rangle, T) = \langle \text{union}(A, A'), b, \text{union}(C, C') \rangle
\]

where \((A', C') = \text{split}(T, b)\)

The function \text{split}(T, b) returns two trees \(A'\) and \(C'\):
\(A'\) contains all elements of \(T\) that are \(< b\)
\(C'\) contains all elements of \(T\) that are \(> b\).

Exercise: define \text{split}, set intersection, set difference.
AVL trees
BST operations are fast as long as the tree is balanced: its height $h$ is small compared to the number of nodes $n$.

We aim for $h = O(\log n)$.

However, some BSTs are completely unbalanced:

```
       1
      / \
     2   3
    / \
   4   5
  /   /
 6    7
```

Such a tree appears naturally when inserting elements 1, 2, . . . , $n$ successively in this order. BST operations, then, take time $O(n)$, as in the case of a sorted list.
Self-balancing trees

The operations (insertion, deletion, etc) should ensure that the tree remains balanced (height proportional to $\log n$) after any sequence of operations.

Idea: at any time, we can perform rotations over sub-trees of a BST.

Rotations preserve the BST property (elements increase from left to right), but can reduce imbalance.
AVL trees

Named after their authors, Georgii Adelson-Velskii and Evgueni Landis.

The AVL criterion: a balancing criterion based on the heights of sub-trees.

For each node \( \langle A, b, C \rangle \), the heights of the sub-trees \( A, C \) differ by at most 1:

\[ |h(A) - h(C)| \leq 1 \]
For each node \( \langle A, b, C \rangle \), the heights of the sub-trees \( A, C \) differ by at most 1.

\[
\begin{align*}
N(h) &= 1 + 2 \times N(h - 1) \\
N(h) &= 2^h - 1
\end{align*}
\]

The height \( h \) is logarithmic in the size \( n = N(h) \) of the tree:
\[ h < \frac{3}{2} \log_2(n + 1). \]
1. Search for the element to be inserted (here, g).
Insertion in an AVL tree: imperative version

1. Search for the element to be inserted (here, g).

1. Search for the element to be inserted (here, g).
1. Search for the element to be inserted (here, \(g\)).
2. Replace the leaf by the node \(\langle \bullet, g, \bullet \rangle\).
1. Search for the element to be inserted (here, $g$).
2. Replace the leaf by the node $\langle \bullet, g, \bullet \rangle$.
3. Go back up the path, updating the heights of nodes ...
Insertion in an AVL tree: imperative version

1. Search for the element to be inserted (here, \( g \)).
2. Replace the leaf by the node \( \langle \bullet, g, \bullet \rangle \).
3. Go back up the path, updating the heights of nodes …
4. … and performing rotations to restore the AVL criterion.
Rotations

Simple rotations: right (if $A$ is too tall), left (if $E$ is too tall).

Double rotations: if $\langle C, d, E \rangle$ is too tall.
A smart constructor \( \text{bal}(A, b, C) \) that builds a BST equivalent to \( \langle A, b, C \rangle \), while performing the required rotations so that it is an AVL, assuming \( |h(A) - h(C)| \leq 2 \) initially.

\[
\text{bal}(A, b, C) = \langle A, b, C \rangle \quad \text{if } |h(A) - h(C)| \leq 1
\]
\[
\text{bal}(\langle A, b, C \rangle, d, E) = \langle A, b, \langle C, d, E \rangle \rangle \\
\quad \quad \quad \text{if } h(A) > h(C), h(A) > h(E)
\]
\[
\text{bal}(\langle A, b, \langle C, d, E \rangle \rangle, f, G) = \langle \langle A, b, C \rangle, d, \langle E, f, G \rangle \rangle \\
\quad \quad \quad \text{if } \max(h(C), h(E)) > h(A) > h(G)
\]

(Plus: 3 symmetric cases.)

We can also define \( \text{bal}^*(A, b, C) \) with no precondition on \( h(A), h(C) \) by iterating \( \text{bal} \) until the resulting tree is an AVL.
Insertion in an AVL tree: algebraic presentation

\[
\text{add}(x, \bullet) = \langle \bullet, x, \bullet \rangle
\]

\[
\text{add}(x, \langle A, b, C \rangle) = \begin{cases} 
\text{bal}(\text{add}(x, A), b, C) & \text{if } x < b \\
\langle A, x, C \rangle & \text{if } x = b \\
\text{bal}(A, b, \text{add}(x, C)) & \text{if } x > b 
\end{cases}
\]

Translates straightforwardly to a pure functional implementation, in time and space \(O(\log n)\) where \(n\) is the size of the tree.

Similar presentation and implementation for deletion in an AVL.
Other balancing criterion

Other criterion for height balancing:

A relaxed AVL criterion:

\[ |h(A) - h(C)| \leq K \]

for each sub-tree \( \langle A, b, C \rangle \)

Example: \( K = 2 \) for the Set and Map OCaml libraries

\( \rightarrow \) fewer rotations than with AVL trees, but longer branches.

Red-black trees (later in this lecture).
Other balancing criterion

Weight balancing:

\[ \frac{1}{K} \leq \frac{w(A)}{w(C)} \leq K \quad \text{for each sub-tree } \langle A, b, C \rangle \]

\( w(A) = 1 + |A| \) is the weight of \( A \) (1 + number of elements).

Example: \( K = 4 \) for the \texttt{Data.Map} Haskell library.

Delicate rotation criteria; several implementations are wrong. (Hirai et Yamamoto, \textit{Balancing weight-balanced trees}, JFP 21(3), 2011.)

Note: AVL trees are not weight-balanced, since we can have \( w(A) \sim 2^h \) (perfectly balanced) and \( w(C) \sim 2F_h \sim c.\varphi^h \) (maximally unbalanced), hence \( w(A)/w(C) \to \infty \) when \( h \to \infty \).
2-3 trees
A different approach to balancing: perfect trees + variable-arity nodes.

• All leaves are at the same level.
• Nodes carry either 2 sub-trees and 1 element or 3 sub-trees and 2 elements.

Examples of 2-3 trees with 3, 4, …, 8 elements:
A generalization of 2-3 trees to trees with a high branching degree:

- All leaves are at the same level.
- Intermediate nodes carry between $k/2$ and $k$ sub-trees.
- The topmost node carries between 2 and $k$ sub-trees.

$k$ is chosen large enough so that one node = one disk block (typically).
2-3 trees: algebraic presentation, lookup algorithm

\[ A, C, E ::= \bullet \quad \text{leaf} \]
\[ | \langle A, b, C \rangle \quad \text{2-node} \]
\[ | \langle A, b, C, d, E \rangle \quad \text{3-node} \]

Lookup in a 2-3 tree: by binary and ternary search

\[
\text{mem}(x, \bullet) = \text{false}
\]

\[
\text{mem}(x, \langle A, b, C \rangle) =
\begin{cases} 
\text{mem}(x, A) & \text{if } x < b \\
\text{true} & \text{if } x = b \\
\text{mem}(x, C) & \text{if } x > b
\end{cases}
\]

\[
\text{mem}(x, \langle A, b, C, d, E \rangle) =
\begin{cases} 
\text{true} & \text{if } x = b \text{ or } x = d \\
\text{mem}(x, A) & \text{if } x < b \\
\text{mem}(x, C) & \text{if } x > b \text{ and } x < d \\
\text{mem}(x, E) & \text{if } x > d
\end{cases}
\]
1. Search for the element to be inserted (here, \texttt{h}).
1. Search for the element to be inserted (here, $h$).

```latex
d
  b
   a  c
  d
   f
    e  g, j
```

1. Search for the element to be inserted (here, $h$).
1. Search for the element to be inserted (here, h).
2. If we end on a 2-node, turn it into a 3-node:
   \( \langle \bullet, g, \bullet \rangle \rightarrow \langle \bullet, g, \bullet, h, \bullet \rangle \) ou \( \langle \bullet, j, \bullet \rangle \rightarrow \langle \bullet, h, \bullet, j, \bullet \rangle \).
1. Search for the element to be inserted (here, \(h\)).
2. If we end on a 2-node, turn it into a 3-node:
   \[\langle \bullet, g, \bullet \rangle \rightarrow \langle \bullet, g, \bullet, h, \bullet \rangle\] ou \[\langle \bullet, j, \bullet \rangle \rightarrow \langle \bullet, h, \bullet, j, \bullet \rangle\].
3. If we end on a 3-node \[\langle \bullet, g, \bullet, j, \bullet \rangle\], “explode” it into two related 2-nodes \[\langle \bullet, g, \bullet \rangle \rightarrow h \rightarrow \langle \bullet, j, \bullet \rangle\] and insert all this in the 2-node above.
Insertion in a 2-3 tree: imperative version

1. Search for the element to be inserted (here, h).
2. If we end on a 2-node, turn it into a 3-node:
   \[
   \langle \bullet, g, \bullet \rangle \rightarrow \langle \bullet, g, \bullet, h, \bullet \rangle \text{ ou } \langle \bullet, j, \bullet \rangle \rightarrow \langle \bullet, h, \bullet, j, \bullet \rangle.
   \]
3. If we end on a 3-node \( \langle \bullet, g, \bullet, j, \bullet \rangle \), “explode” it into two related 2-nodes \( \langle \bullet, g, \bullet \rangle - h - \langle \bullet, j, \bullet \rangle \) and insert all this in the 2-node above.
Insertion in a 2-3 tree: imperative version

1. Search for the element to be inserted (here, h).
2. If we end on a 2-node, turn it into a 3-node:
   \[
   (\bullet, g, \bullet) \rightarrow (\bullet, g, \bullet, h, \bullet) \text{ ou } (\bullet, j, \bullet) \rightarrow (\bullet, h, \bullet, j, \bullet).
   \]
3. If we end on a 3-node \((\bullet, g, \bullet, j, \bullet)\), “explode” it into two related 2-nodes \((\bullet, g, \bullet) - h - (\bullet, j, \bullet)\) and insert all this in the 2-node above.
1. Search for the element to be inserted (here, \(h\)).
2. If we end on a 2-node, turn it into a 3-node:
   \(<\bullet, g, \bullet> \rightarrow <\bullet, g, \bullet, h, \bullet>\) ou \(<\bullet, j, \bullet> \rightarrow <\bullet, h, \bullet, j, \bullet>\).
3. If we end on a 3-node \(<\bullet, g, \bullet, j, \bullet>\), “explode” it into two related 2-nodes \(<\bullet, g, \bullet> - h - <\bullet, j, \bullet>\) and insert all this in the 2-node above.
4. If the node above is a 3-node, explode it too and iterate.
All cases of insertion in leftmost position in a 2-3 tree of height 2

2-2 path becomes 2-3:

```
    c
   /\  
  b  D  a, b  D
```

3-2 path becomes 3-3:

```
    c, e
   /\    /\ 
  b  D  F  a, b  D  F
```

2-3 path becomes 3-2:

```
    d
   /\  
  b, c  E  a  c  E
```

3-3 path becomes 2-2-2:

```
    d
   /\  /\ 
  b, c E  a  c  E  G
```

Note: similar to carry propagation when incrementing a base-2 number.
A purely functional, finely-typed implementation

Using generalized algebraic data types (GADTs) from Haskell and OCaml to enforce the height invariant.

```ocaml
type zero = Zero
type 'a succ = Succ of 'a

type _ tree =
  | Leaf : zero tree
  | Two : 'h tree * elt * 'h tree -> 'h succ tree
  | Three : 'h tree * elt * 'h tree * elt * 'h tree
          -> 'h succ tree
```

The 'h parameter in type 'h tree is the height of the tree, encoded in types as a Peano integer:
zero (= 0), zero succ (= 1), zero succ succ (= 2), etc.
A purely functional, finely-typed implementation

Using generalized algebraic data types (GADTs) from Haskell and OCaml to enforce the height invariant.

```ocaml
type zero = Zero

type 'a succ = Succ of 'a

type _ tree =
| Leaf : zero tree
| Two : 'h tree * elt * 'h tree -> 'h succ tree
| Three : 'h tree * elt * 'h tree * elt * 'h tree
       -> 'h succ tree
```

The types of constructors Leaf, Two, Three enforce the height invariant.
A purely functional, finely-typed implementation

Using generalized algebraic data types (GADTs) from Haskell and OCaml to enforce the height invariant.

```ocaml
type zero = Zero
type 'a succ = Succ of 'a

type _ tree =
| Leaf : zero tree
| Two : 'h tree * elt * 'h tree -> 'h succ tree
| Three : 'h tree * elt * 'h tree * elt * 'h tree
          -> 'h succ tree

type set = Set : 'h tree -> set

A finite set (type set) is an 'h tree for some 'h
(existential quantification).
```
Type-checking insertion

The result of insertion is not just a tree but an etree: either Ok if the result is a well-formed 2-3 tree, or Split if it’s the outcome of exploding a node.

```
type _ etree =
  | Ok: 'h tree -> 'h etree
  | Split: 'h tree * elt * 'h tree -> 'h etree
```

The difference between Split and Two is that Two is a tree of height $h + 1$, while Split is considered as having height $h$. 
let rec add_t : type h. elt -> h tree -> h etree =
  fun x t ->
  match t with
  | Leaf -> Split(Leaf, x, Leaf)
  | Two(a, b, c) ->
    if x = b then Ok t else
    if x < b then two1(add_t x a, b, c)
    else two2(a, b, add_t x c)
  | Three(a, b, c, d, e) ->
    if x = b || x = d then Ok t else
    if x < b then three1(add_t x a, b, c, d, e)
    else if x < d then three2(a, b, add_t x c, d, e)
    else three3(a, b, c, d, add_t x e)
Smart constructors to absorb explosions

two1: \('h\) etree * elt * \('h\) tree -> \('h\) succ etree

two2: \('h\) tree * elt * \('h\) etree -> \('h\) succ etree

three1: \('h\) etree * elt * \('h\) tree * elt * \('h\) tree -> \('h\) succ etree

two2: \('h\) tree * elt * \('h\) etree * elt * \('h\) tree -> \('h\) succ etree

two3: \('h\) tree * elt * \('h\) etree * elt * \('h\) etree -> \('h\) succ etree

Definitions guided by the types and the BST invariant.

For instance:

let two1 (ll, x, r) =
    match ll with
    | Ok l -> Ok (Two(l, x, r))
    | Split(a, b, c) -> Ok (Three(a, b, c, x, r))

let three1 (ll, x, m, y, r) ->
    match ll with
    | Ok l -> Ok (Three(l, x, m, y, r))
    | Split(a, b, c) -> Split(Two(a, b, c), x, Two(m, y, r))
At the top level, for sets instead of raw trees:

```ocaml
define add : elt -> set -> set =
    fun x (Set t) ->
        match add_t x t with
        | Ok t' -> Set t'
        | Split(a, b, c) -> Set (Two(a, b, c))
```

The second case increases height by one, but this is hidden by the `Set` constructor, which quantifies existentially over the height.
Deletion in a 2-3 tree

Just like insertion can “explode” a 3-node, deletion can “implode” a 2-node because its height needs to decrease by 1.

\[ \langle \bullet, a, \bullet, b, \bullet \rangle \rightarrow \langle \bullet, b, \bullet \rangle \quad \checkmark \quad \langle \bullet, a, \bullet \rangle \rightarrow \bullet \quad \times \]

We must absorb this height reduction further “up” the tree:
Deletion in a 2-3 tree

The result of deletion is not just a tree but an etree:

```ocaml
type _ etree =
  | Ok: 'h tree -> 'h etree
  | Short: 'h tree -> 'h succ etree
```

Short \( t \) is a short tree \( t \), with height \( h \) instead of the expected \( h + 1 \). This wrong height must be absorbed by smart constructors:

```ocaml
two1: 'h etree * elt * 'h tree -> 'h succ etree
two2: 'h tree * elt * 'h etree -> 'h succ etree
three1: 'h etree * elt * 'h tree * elt * 'h tree -> 'h succ etree
three2: 'h tree * elt * 'h etree * elt * 'h tree -> 'h succ etree
three3: 'h tree * elt * 'h tree * elt * 'h etree -> 'h succ etree
```

Deletion follows the same pattern as insertion. (Exercise.)
Red-black trees
Red-black trees

Binary search trees where each node has a color: red or black.

Two invariants over colors:
1. The children of a red node are not red.
2. All paths from the root to a leaf contain the same number of black nodes.
   This number is called the black height of the tree.
Red-black trees are balanced

1. The children of a red node are not red.
2. All paths from the root to a leaf contain the same number of black nodes.

Let $h$ be the black height of the tree. Then, all paths from the root to a leaf have lengths $h$ to $2h + 1$. This ensures that the tree contains at least $2^h - 1$ nodes, and therefore that it is balanced.

This can be proved by considering maximally-unbalanced trees:
Red-black trees and 2-3-4 trees

Red-black trees were introduced by L. J. Guibas and R. Sedgewick (1978) as a simplified representation for 2-3-4 trees, that is, B-trees of degree 4, where each node carries from 2 to 4 sub-trees and from 1 to 3 keys.

Node 2:

Node 3:

Node 4:
Symmetrically, we recover a 2-3-4 tree from a red-black tree by lifting the red nodes to the same level as their black parents:
Algebraic presentation

Color: \( k ::= \text{R} \mid \text{B} \) \hspace{1cm} \text{red, black}

Red-black tree: \( A, C ::= \bullet \mid k\langle A, b, C \rangle \)

Standard binary search, ignoring colors:

\[
\begin{align*}
\text{mem}(x, \bullet) &= \text{false} \\
\text{mem}(x, k\langle A, b, C \rangle) &= \begin{cases} 
\text{mem}(x, A) & \text{if } x < b \\
\text{true} & \text{if } x = b \\
\text{mem}(x, C) & \text{if } x > b 
\end{cases}
\end{align*}
\]

Performs the same comparisons as binary/ternary/quaternary search in the corresponding 2-3-4 tree.
Insertion in a red-black tree

Same approach as for AVL trees:

- Search for the element $x$ to be inserted.
- If we reach a leaf, we replace it with $\text{R}(\bullet, x, \bullet)$.
- Restore the color invariants on the way “up” ($\text{bal}$ function).
- Recolor the root to black. (This fixes red-red violations at the top.)

$$
\text{add}(x, \bullet) = \text{R}(\bullet, x, \bullet)
$$

$$
\text{add}(x, k\langle A, b, C \rangle) = \begin{cases} 
\text{bal}(k, \text{add}(x, A), b, C) & \text{if } x < b \\
\text{add}(x, A, b, C) & \text{if } x = b \\
\text{bal}(k, A, b, \text{add}(x, C)) & \text{if } x > b 
\end{cases}
$$
Restoring color invariants by rotations and recoloring

In algorithmic textbooks: 8 cases or more.
C. Okasaki (1999): 4 cases are enough.
Rebalancing in algebraic notation

\[
\text{bal}(\mathbf{B}, \mathbf{R} \langle \mathbf{R} \langle \mathbf{A}, b, C \rangle, d, E \rangle, f, G) = \mathbf{R} \langle \mathbf{B} \langle \mathbf{A}, b, C \rangle, d, \mathbf{B} \langle E, f, G \rangle \rangle \\
\text{bal}(\mathbf{B}, \mathbf{R} \langle \mathbf{A}, b, \mathbf{R} \langle C, d, E \rangle \rangle, f, G) = " " " " \\
\text{bal}(\mathbf{B}, \mathbf{A}, b, \mathbf{R} \langle \mathbf{R} \langle C, d, E \rangle, f, G \rangle) = " " " " \\
\text{bal}(\mathbf{B}, \mathbf{A}, b, \mathbf{R} \langle C, d, \mathbf{R} \langle E, f, G \rangle \rangle) = " " " " \\
\text{bal}(c, \mathbf{A}, b, C) = c \langle A, b, C \rangle \quad \text{in all other cases}
\]
Deletion in a red-black tree

Same algorithm as for AVL trees:

- Find the sub-tree $k\langle A, x, C \rangle$ carrying $x$, the element to be removed.
- Replace it with $k\langle A, \text{min}(C), \text{delmin}(C) \rangle$.
- Rebalance (restore invariants) on the way up.

However, rebalancing is much more complicated than for insertion (12 different cases or more).
Explaining deletion with “double black” nodes

(K. Germane et M. Might, *Deletion: the curse of the red-black tree*, JFP 24(4), 2014.)

Intermediate results of deletion can be not only red-black trees, but also

- a “double” leaf ●●, which counts as 1 black node;
- a “double black” node BB⟨A, b, C⟩ (drawn in white!), which counts as 2 black nodes.

During rebalancing, these double nodes and leaves propagate upwards (while preserving red-black invariants) before being absorbed eventually.
Deleting the smallest element

Base case: (preserving the black height)

\[ \text{R}\langle \bullet, x, \bullet \rangle \rightarrow \bullet \quad \text{B}\langle \bullet, x, \bullet \rangle \rightarrow \bullet \bullet \]

Propagating \bullet \bullet upwards: (plus: left-right symmetric cases)

![Diagram showing the deletion process and propagating black height rules.](image-url)
Propagating double black nodes upwards
Tries
Tries (also known as prefix trees)

(From *information reTRIEval.*)

A representation of finite sets or finite maps whose keys are words, that is, lists of symbols.

For instance:

- **character strings**
  (symbols = characters, or bytes, or bits)
- **integer numbers**
  (symbols = bits or groups of *k* bits).

Each node of a trie has between 0 and *K* sub-tries, each labeled by a symbol.  \((K = \text{number of different symbols})\)
An example of a trie

The set comprising the words **and, ant, anti, do, does**.

Black nodes (●) mark the end of a word.
An example of a trie

The set comprising the words **and, ant, anti, do, does.**

Searching: follow the edges that spell out the word. The word belongs to the set iff we end on a black node.
The set comprising the words **and, ant, anti, do, does.**

Persistent insertion: copy and complete the branch that spells out the word. Mark the final node black.

(Example: inserting **doe** and **did**.)
Purely functional implementation of tries

Sets and maps:

```ocaml
type set = Node of bool * (char * set) list
type 'a map = Node of 'a option * (char * 'a map) list
```

char is the type of symbols. Sub-trees are organized as association lists (char * ...) list.

Special case when symbols are bits:

```ocaml
type set = Empty | Node of set * bool * set
type 'a map = Empty | Node of 'a map * 'a option * 'a map
```

Always two sub-trees, one for bit 0, the other for bit 1.
let rec mem s t =
  match t, s with
  | Empty, _ -> false
  | Node(_, acc, _), [] -> acc
  | Node(l, _, r), b :: s' -> mem s' (if b then r else l)

let rec add s t =
  match t, s with
  | Empty -> add s (Node(Empty, false, Empty))
  | Node(l, acc, r), [] -> Node(l, true, r)
  | Node(l, acc, r), b :: s' ->
    if b then Node(l, acc, add s' r)
    else Node(add s' l, acc, r)

Time proportional to $|s|$. If comparing two keys is expensive, tries are more efficient than BSTs (time $O(|s| \log n)$).
In an immutable trie, sub-tries corresponding to suffixes common to several words can be shared, obtaining a directed acyclic word graph (DAWG), also known as deterministic acyclic finite-state automaton (DAFSA).

Example: bon, mon, ma, mes, ton, ta, tes.

Construction: using hash consing or automata minimization.
Compressed trie

To avoid trivial nodes, we can label each sub-trie not by a single symbol but by a sub-word (= a list of symbols).
To avoid trivial nodes, we can label each sub-trie not by a single symbol but by a sub-word (= a list of symbols).

Insertion can require splitting an edge into an edge-node-edge in order to provide an anchor point for the new word (did in the example above). We split at the largest common prefix between the sub-word on the edge (do) and of the new word (did).
PATRICIA trees

(Donald R. Morrison, PATRICIA – Practical Algorithm to Retrieve Information Coded in Alphanumeric, 1968.)

Tries indexed by bit strings (integers), optimized for sparse tries.

Each node carries the number of a bit to test (+ the prefix).

Keys are stored at the leaves.
(Phil Bagwell, Ideal Hash Trees, 2000.)

To represent sets \( \{k_1, \ldots, k_n\} \) of keys of any type, we can transform these keys into bit strings (integers) using a hash function \( H \), and store \( k_1, \ldots, k_n \) at the leaves of a PATRICIA trie, with positions \( H(k_1), \ldots, H(k_n) \).

Where \( H("lorem") = 000000111011, H("dolor") = 000010101011 \), etc.
Handling collisions

The hash function $H$ takes finitely many values (typically, 32 or 64-bit integers). Hence there exists collisions: two different keys $k \neq k'$ that hash to the same bit string $H(k) = H(k')$.

Standard solution: at the leaves of the trie, put lists of keys $k, k', k'', \ldots$ that hash to the same value.

Bagwell’s solution: “extend” the hash value by using several statistically-independent hash functions $H_0, H_1, \ldots$ In other words, we compute (on demand) a very long hash value $H_0(k).H_1(k) \ldots H_n(k) \ldots$ and we use the PATRICIA tree to distinguish between these hash values.
Instead of a PATRICIA trie, HAMTs use a simple trie, but with a high branching degree, for instance $32 = 2^5$, hence hash values $H(k)$ are processed by groups of 5 bits.

\[
b_0 b_1 b_2 b_3 b_4
\]

\[
b_5 b_6 b_7 b_8 b_9
\]

(where $H(k) = b_0 b_1 b_2 \ldots$)
Hash Array Mapped Tries

Every node carries a partial function \( f : [0, 31] \rightarrow \text{trie} \) implemented efficiently in space and in time as:

- A bit-vector \( B \) of size 32 (= a 32-bit machine integer). For each \( i \in [0, 31] \), \( B(i) \) says whether \( f(i) \) is defined or not.
- An array \( T \) of \( n \) sub-tries, where \( n \) is the number of \( i \)'s where \( f(i) \) is defined.

Accessing the sub-trie labeled \( i \) is very efficient:

\[
f(i) = \begin{cases} 
\text{undefined} & \text{if } B \& (1 \ll i) = 0 \\
T[\text{popcnt}(B \& ((1 \ll i) - 1))] & \text{otherwise}
\end{cases}
\]

\( \text{popcnt}(n) \) is the Hamming weight of \( n \) (number of 1 bits).
Summary
Using examples based on balanced trees, we saw two complementary approaches to developing persistent data structures:

1. Start from **imperative, ephemeral data structures** and introduce **path copying** to make them persistent.

2. Start from **algebraic definitions** of the data structure and its operations, and derive **purely functional implementations**.

Both approaches produce the same algorithms.

(2) facilitates specification and functional verification.

(1) is traditionally used for complexity analysis.

(⇒ seminar by T. Nipkow)
Persistent data structures with purely functional implementations for

- dictionaries, finite sets, finite maps;
- priority queues;
- indexed sequences.

All elementary operations run in time $O(\log n)$.

A recurring question in later lectures: how to improve on $O(\log n)$?
